# Timer obscure behaviour

# **Timer Global Circuit**

# **Relation between Timer and Divider register**

This is a schematic of the circuit involving TAC and DIV:

Notice how the values that are connected to the inputs of the multiplexer are the values o those bits, not the carry of those bits. This is the reason of a few things:

- When writing to DIV, the whole counter is reset, so the timer is also affected.
- When writing to DIV, if the current output is 1 and timer is enabled, as the new value after reseting DIV will be 0, the falling edge detector will detect a falling edge and TIMA will increase.
- When writing to TAC, if the previously selected multiplexer input was 1 and the new
  input is 0, TIMA will increase too. This doesnt happen when the timer is disabled, bu
  also happens when disabling the timer (the same effect as writing to DIV). The
  following code explains the behaviour in DMG and MGB.

```
clocks_array[4] = {1024, 16, 64, 256}
old_clocks = clocks_array[old_TAC&3]
new_clocks = clocks_array[new_TAC&3]
old_enable = old_TAC & BIT(2)
new_enable = new_TAC & BIT(2)
sys_clocks = 16 bit system counter
```

```
IF old_enable == 0 THEN
    glitch = 0 (*)
ELSE
    IF new_enable == 0 THEN
        glitch = (sys_clocks & (old_clocks/2)) != 0
ELSE
        glitch = ((sys_clocks & (old_clocks/2)) != 0) && ((sys_clocks & (new_clocks END IF
END IF
```

The sentence marked with a (\*) has a different behaviour in GBC (AGB and AGS seem to have strange behaviour even in the other statements). When enabling the timer and maintaining the same frequency it doesnt glitch. When disabling the timer it doesnt glitch either. When another change of value happens (so timer is enabled after the write), the behaviour depends on a race condition, so it cannot be predicted for every device.

## **Timer Overflow Behaviour**

When TIMA overflows, the value from TMA is loaded and IF timer flag is set to 1, but this doesnt happen immediately. Timer interrupt is delayed 1 cycle (4 clocks) from the TIMA overflow. The TMA reload to TIMA is also delayed. For one cycle, after overflowing TIMA, the value in TIMA is 00h, not TMA. This happens only when an overflow happens, not whe the upper bit goes from 1 to 0, it cant be done manually writing to TIMA, the timer has to increment itself.

For example (SYS is the system internal counter divided by 4 for easier understanding, ea increment of the graph is 1 cycle, not 1 clock):

Timer overflows:

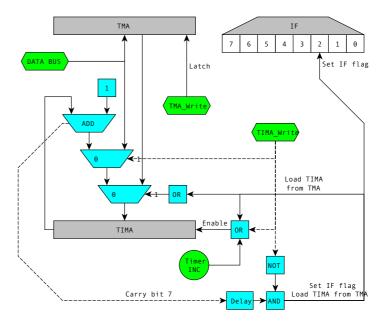

```
[A] [B]
SYS FD FE FF | 00 | 01 02 03
TIMA FF FF FF | 00 | 23 23 23
TMA 23 23 23 23 23 23 23
IF E0 E0 E0 | E0 | E4 E4 E4

Timer doesn't overflow:

[C]
SYS FD FE FF 00 01 02 03
TIMA 45 45 45 46 46 46 46 46
TMA 23 23 23 23 23 23 23 23
```

E0 E0 E0 E0 E0 E0

- During the strange cycle [A] you can prevent the IF flag from being set and prevent t TIMA from being reloaded from TMA by writing a value to TIMA. That new value will be the one that stays in the TIMA register after the instruction. Writing to DIV, TAC of their registers wont prevent the IF flag from being set or TIMA from being reloaded
- If you write to TIMA during the cycle that TMA is being loaded to it [B], the write wil be ignored and TMA value will be written to TIMA instead.
- If TMA is written the same cycle it is loaded to TIMA [B], TIMA is also loaded with th
  value.
- $\bullet\,$  This is a guessed schematic to explain the priorities with registers TIMA and TMA:

TMA is a latch. As soon as it is written, the output shows that value. That explains that wh TMA is written and TIMA is being incremented, the value written to TMA is also written to TIMA. It doesnt affect the IF flag, though.
